## **A Study of the Absorption of Water into Brick and Mortar Samples Treated with Damp Proofing Creams**

When a porous building element is in direct contact with the ground, the process of rising damp can occur where water is drawn upwards into the building structure by capillarity. The height of this capillary rise will depend on a number of factors including the pore structure of the building element and the evaporation rate from the surface.

One method of controlling rising damp is to inject silicone based products into the mortar line of brickwork. These products work by diffusing into the porous structure and chemically reacting with the mineral surface to attach hydrophobic groups. The groups then reduce the surface energy inside the capillaries which causes the rising damp boundary to fall - thus reducing dampness.

### **Background to testing**

In 2000 a silicone based solventless cream product called Dryzone was launched with the ability to control rising damp. This contains a high level of material (63% by weight). Since then, alternative products have come on the market at lower cost but with lower amounts of active material (15-20% by weight).

The University were asked to compare the water absorption of brick assemblies that had been treated with high strength and low strength creams.

Damp proofing creams are used to treat older houses which have experienced rising damp problems. The mortar found in such properties is quite often porous and neutral in pH. This is because the alkalinity of the lime or cement has been reduced gradually by the process of carbonation. In these experiments a mortar recipe was chosen with high porosity and neutral pH to replicate this condition.

### **Sample preparation**

Brick assemblies - referred to as "Brick Burgers" - were prepared from a sandwich of two brick slips and wet mortar.

The brick slips were supplied by Hanson PLC. Common fletton brick faces were used of size 215 mm x 65 mm x 16 mm. The mortar used was prepared from plastering sand supplied by a local merchant. This was bound with a neutral pH inorganic binder. The particle size distribution of the sand is given in the Appendix

After the "burger" had been made up, two wooden dowels were inserted into the mortar to form holes that could be used to place the damp proofing creams. The holes were of diameter 12mm and were placed 120 mm apart from centre-to-centre. The wooden dowels were removed within 5 minutes of making the burger. Each burger was then left to cure in air for 28 days at 20C.

Then 5 g of each damp proofing cream was inserted into each hole by using a plastic dropping pipette. The assembly was then left to cure for 28 days

---

**Water absorption testing**

The water absorption of the brick burgers was measured by placing a burger in a shallow tray of water of approximately 4 mm depth. The weight gain was measured periodically to give a water absorption graph. In addition, photographs and a time-lapse video were taken to show how the rising damp boundary advanced with time.

Graph

The graph below shows the observed weight gain from burgers made with low and high strength creams. The original weight and time data are shown in Appendix 2.

**Figure 1 : Weight gain on contact with water of brick assemblies treated with high and low strength damp proofing creams**

Most of the absorption occurs within the first 500 minutes of contact with water. After this point there is a levelling off to a plateau value.

The data shows a clear difference in water absorption behaviour of the high and low strength creams

As the rate of absorption is governed by diffusion of water into the pores, it is worthwhile plotting the data against the square root of time (Fick's Law). This is shown in Appendix 3 where again similar differences are observed. By treating the data in this way it is possible to calculate the diffusion rate coefficients as follows;

D3	Initial Gradient = 2.78
Coefficient of Diffusion,	$D = \frac{\pi}{16} \left( \frac{M_t}{M_\infty} \frac{h}{\sqrt{t}} \right)^2$
	= 1.52 mm <sup>2</sup> /s

W3	Initial Gradient = 16.42
Coefficient of Diffusion,	$D = \frac{\pi}{16} \left( \frac{M_t}{M_\infty} \frac{h}{\sqrt{t}} \right)^2$
	= 52.93 mm <sup>2</sup> /s

This coefficient is calculated by measuring the initial gradient from the graph and proportioning by a thickness related term.

Hence we see that;

Coefficient of diffusion for high strength cream =  $1.52 \text{ mm}^2/\text{s}$

Coefficient of diffusion for low strength cream =  $52.93 \text{ mm}^2/\text{s}$

### Photographs

It was possible to watch the advancing rise of water in the brick assemblies. Where water has wetted the brick and mortar surface a darker colour is evident. The pictures on the following page were initially taken at 15 minute intervals and then at longer times. It can be seen that water absorption occurs quickly.

#### **Photograph: Water absorption in the early part of the test**

### Time-lapse video

A time-lapse video was taken of the water rise. Single shots were taken every 10 seconds and then converted into a "mpg" file using Antechinus Animator and TMPGEnc 3.0 Xpress software.

This time-lapse video file entitled SAFEGUARD TIMELAPSE.mpg is available from the University of Portsmouth

### **Conclusions**

The data shows the following points;

1. Water absorption occurs in both brick and mortar elements of the test materials.
2. The higher strength damp proofing creams are effective at reducing this absorption. Low strength creams appear to have minimal effect.
3. It is possible to model water absorption by classical diffusion equations. In the particular cases tested here, the two diffusion coefficients measured were  $1.52 \text{ mm}^2/\text{s}$  for high strength cream and  $52.93 \text{ mm}^2/\text{sec}$  on low strength cream.
